⁽⁵⁴⁾ Hybrid receptors, nucleic acid encoding them, their preparation, and their use in determination of ligands and their antagonists and agonists.

⁽⁵⁷⁾ Hybrid receptors, produced by recombinant DNA technology, comprise (a) the ligand binding domain of a predetermined receptor and (b) a heterologous reporter polypeptide. The hybrid receptors are useful for convenient and large scale assay of biologically active ligands or their antagonists or agonists. (a) may be the extracellular domain of the receptor, or a cytoplasmic domain of a receptor or oncogene. (b) may be an enzyme. A transmembrane domain may be interposed between (a) and (b).

HYBRID RECEPTORS, NUCLEIC ACID ENCODING THEM, THEIR
PREPARATION, AND THEIR USE IN DETERMINATION OF LIGANDS
AND THEIR ANTAGONISTS OR AGONISTS

This invention relates to methods for screening candidate drugs for their ability to bind a receptor in such a fashion as to mimic or antagonize the function of a ligand which ordinarily interacts with the receptor <u>in vivo</u>. It also relates to methods for the functional assay of ligands.

Receptors are defined as proteinaceous macromolecules located on cell membranes that perform a signal transducing function. Many receptors are located on the outer cell membrane. These cell surface receptors have extracellular and cytoplasmic domains wherein the extracellular domain is capable of specifically binding a substance so that the cytoplasmic domain interacts with another cell molecule as a function of the binding of the substance by the extracellular domain. The substance which is bound by the receptor is called a ligand, a term which is definitionally meaningful only in terms of its counterpart receptor. The term "ligand" does not imply any particular molecular size or other structural or compositional feature other than that the substance in question is capable of binding,

cleaving or otherwise interacting with the receptor in such a way that the receptor conveys information about the presence of the ligand to a target molecule. Stated alternatively, not all substances capable of binding a receptor are ligands, but all ligands are capable of binding a receptor. Receptors do not include such substances as immunoglobulins.

Receptors typically are divided structurally into three domains. A highly hydrophobic region of about 20 to 25 residues which is believed to be responsible for embedding the receptor in the cell membrane is flanked on its amino and carboxyl termini by regions that respectively extend into the extracellular and cytoplasmic environment. The extracellular region includes the ligand binding domain. The cytoplasmic region includes a domain for effecting a change in the cytoplasm. Typically, the cytoplasmic region includes an enzymatic function that is activated by receptor aggregation or conformational changes brought on by ligand binding.

Receptors are believed to function by a process variously termed activation or signal transduction. A ligand binds to the extracellular ligand binding domain in such a way that the conformation of the receptor molecule changes within the cytoplasmic region. This conformational change, called activation, modifies the effect of the receptor on cytoplasmic components. Among changes brought about by receptor activation are changes in or development of receptor enzymatic activity.

The pharmaceutical industry in recent years has oriented its research to focus on the role of receptors in disease or injury and to design drugs, generally low molecular weight substances, that are capable of binding to the receptors. Drugs identified in this initial screen are then tested for the desired activity in vivo or in tissue explants. As a result, conventional

t chniques do not lend thems lves to large scale screening. Tissue samples or isolated cells containing the targ t rec ptors, e.g. heart atrial tissue, are costly to obtain, present in limited quantity, and difficult to maintain in a functionally viable Additionally, it is often difficult to reliably and reproducibly administer the candidate drug to tissue samples. Screening assays using primary explants in tissue culture are undertaken in larger scale than is possible with tissue samples. However, it is more difficult to assay physiological effect and the assays are subject to interference from many sources, e.g. culture media or cultivation conditions. Finally, assays using receptors isolated from natural materials have the disadvantage that the receptor is subject to natural variability and suitable natural sources may not always be available. It is an object herein to provide readily reproducible, simple assay systems that can be practiced on a large scale for determining not only ligand binding but also the character of the binding as agonistic or antagonistic.

20

25

30

35

5

10

15

Similarly, meaningful clinical diagnosis often depends upon the assay of biologically active ligand without interference from inactive forms of the ligand, for example, ligands that have been subject to enzymatic or other processes of the test subject that change or even eliminate the activity of the ligand. Immunoassay methods are widely used in determining ligands in test samples. However, it is often quite difficult to identify antibodies that are able to discriminate between the active and inactive forms of a ligand. Receptors have infrequently been used in place of antibodies as analyte binding reagents. However, not all substances that bind to receptors are necessarily capable of inducing receptor activity, i.e. active biologically. object herein to provide a method that will identify ligands in clinical test samples which are active in inducing or inhibiting signal transduction by their receptors.

Many receptors have been identified that have at least known in vitro assayable activity that is dependent upon For example, the binding of EGF to the ligand interaction. epidermal growth receptor stimulates a phosphotransferase domain in the receptor to phosphorylate certain target amino acid residues located in its intracellular cytoplasmic domain, a process called autophosphorylation. Receptors also are known to antibodies or specific cytoplasmic substrate phosphorylate polypeptides that bind to the region in which their phosphotrans-Unfortunately, other receptors ferase active site is located. have no known ligand-dependent enzymatic activity, notwithstanding that they are known to bind ligands with high affinity, or their activity is so low that it is difficult to quantitatively assay ligand-dependent activation. It may be desirable for therapeutic purposes to antagonize or agonize a ligand interaction with such cryptic receptors but, in the absence of the tissue concerned or, in some cases an intact organism, no method is available for determining whether a candidate drug is simply binding the receptor in a function-neutral fashion, nor whether the candidate is binding as an agonist or antagonist. Accordingly, it is an object to provide a method for screening candidate drugs for ligand agonist or antagonist activity where the receptor for the ligand exhibits no known signal transduction characteristic.

25

15

Summary

These objects are accomplished by the use of a novel receptor hybrid comprising the ligand binding domain of a receptor fused to a heterologous reporter polypeptide which is capable of undergoing an assayable change in conformation or function when the ligand binding domain of the receptor binds to either the ligand or to an agonist or antagonist of the ligand.

If a disease or injury is the result of a ligand acting on a given r ceptor, the objective will be to identify substances capable of counteracting the ligand's effect on the critical receptor, i.e., ligand antagonists. On the ther hand, a model therapy for a clinical condition characterized by insufficient ligand activity would consist of drugs that enhance or supplement a defective or absent ligand, i.e., ligand agonists.

The hybrid receptor of this invention is useful in screening methods for identifying receptor-active agonistic drugs. One incubates the hybrid receptor with the candidate drug and assays for the generation of a signal by the heterologous reporter polypeptide. Generally, but not necessarily, the signal generated by the reporter polypeptide is assayed as an activation or stimulation of an enzymatic function of the reporter polypeptide. It is not necessary to include standards having known amounts of ligand unless one wishes to quantify the agonist activity of the candidate; in fact, the ligand which modulates the receptor activity in vivo may be completely unknown. It is one of the benefits of this assay system that neither the ligand for the receptor nor the in vivo signal transducing mechanism of the receptors need be known in order to identify agonist drugs.

The hybrid receptor is used to assay amounts of biological ligand in test samples in the same fashion as one screens for agonist drugs. Since this utility, by definition, contemplates a known ligand, then a standard curve using known amounts of ligand is prepared and compared with the test sample results.

Antagonist drug candidates are selected by the same assay as is used for identifying agonists, except that here the hybrid receptor is incubated with a known receptor agonist. The agonist, which may be a drug or the normal in vivo ligand, is

5

10

15

20

25

30

incubated with the receptor before or, preferably, simultaneous with contacting the receptor with the candidate drug. Antagonist activity is a function f th displacement of agonist or ligand activity as measured by changes in the reporter polypeptide.

5

A particular advantage of the hybrid receptor is that it enables a universal, portable assay system for any ligand-receptor interaction. This invention contemplates, for example, that the cytoplasmic domain of a first receptor is selected as the portable reporter polypeptide. This domain is then substituted for the cytoplasmic domain of other receptors in preparing the hybrid receptors of the invention. The assay system, e.g. autophosphorylation assay, useful with the first receptor is then available for use with all other hybrid receptors containing the cytoplasmic domain of the first receptor.

35

Figure la depicts the composition of a plasmid employed in the expression of hybrids of the insulin and epidermal growth factor receptors. The region coding for different receptor mutants is shown by a shaded bar (cDNA). Early SV40 promoter sequences shown by heavy black arrows and polyA addition sites have been marked. The dihydrofolate reductase (DHFR) coding sequence (Simonsen and Levinson, 1983, "Proc. Natl. Acad. Sci. USA" 80:2495-2499) and restriction sites used for plasmid constructions are shown. Expression of both cDNAs was controlled by promoter sequences of the Simian virus (SV) 40 early region and by 3'-untranslated sequences of the gene coding for the hepatitis B virus surface antigen (Crowley et al., 1983, "Mol. Cell. Biol." 3: 44-45). Sequences of the E. coli plasmid pML (a pBR322 derivative suitable for use in mammalian cells; Lusky and Botchan, 1981, "Nature" 293:79) containing the origin of replication and the ampicillin resistance gene were present to allow plasmid replication in E. coli.

Figure 1b is a schematic comparison of insulin (HIR) and EGF (HER) receptors and a hybrid receptors IER and IGER prepared Human EGF receptor (HER), human insulin receptor therefrom. (HIR), insulin-EGF receptor chimera (IER), and insulin- α -subunit-EGF receptor chimera (IoER) cDNAs are represented by horizontal lines and coding sequences shown as a dotted box for HIRa sequences (α) , as a shaded box for HIR β , and as an open box for HER sequences. The coding regions have been aligned at the transmembrane domain (not shown in scale). The coding segment for the protein signal sequence is marked by (S) and the precursor cleavage sites are indicated by a vertical line. The junction of the heterologous receptor cDNAs is shown by a zigzag line and synthetic oligonucleotides used at the junctions are represented by black bars. DNA restriction endonuclease cleavage sites relevant for the constructions are marked on top of the cDNA sequences.

Figure 2 illustrates that ¹²⁵I insulin binding to COS-7 cells increases when the COS-7 cells are transfected with the cDNA constructs of Figure 1a, 'compared to cells transfected with a control expression vector.

Figures 3a-3d are SDS PAGE reducing electrophoresis gels of autophosphorylated detergent lysates obtained from various transformed and control cells and immunoprecipitated with appropriate antibodies as noted in the Example. The (+) and (-) gels represent insulin or (in the case of A431) EGF-treated receptors. Numbers in the margins are marker molecular weights. Fig. depicts the anti-HER immunoprecipitated autophosphorylation products of mock-transformed controls and recombinant transformant cells. This demonstrates expression of hybrid insulin-EGF receptor constructs in the recombinants.

Figure 3b demonstrates that the autophosphorylation of the hybrid containing the complete xtracellular domain of the insulin receptor is activated by insulin.

5

Figure 3c depicts the kinetics of the insulin-activated autophosphorylation of the IER receptor. It shows that the autophosphorylation observed is dependent upon the time of the phosphorylation reaction.

10

Figure 3d illustrates the change in SDS-PAGE migration of the IER receptor after insulin activation.

15

Figure 4 depicts the structure of HER-erbB, a hybrid receptor containing the epidermal growth factor extracellular domain and a fragment of the erbB oncogene to serve as the reporter molecule.

20

Figure 5 depicts electrophoresis gels demonstrating autophosphorylation of a hybrid oncogene-receptor construct in the presence (+) or absence of ligand (EGF)(-).

Detailed Description

25

30

The hybrid receptor is the core of the methods described herein. It principally comprises a ligand binding domain and a reporter polypeptide. The ligand binding domain is located within the extracellular region of a receptor. It is often difficult to identify the precise amino acid sequences involved in ligand binding. In fact, several regions may be involved in ligand binding, particularly where the ligand is a polypeptide. Thus, it is preferred that the entire extracellular region of the receptor be assembled into the hybrid. This also will help to ensure that the ligand binding domain is maintained in its proper conforma-

tion.

5

10

15

20

25

Suitable ligand binding domains are selected in any one First, when one intends to use the hybrid to of several ways. assay for a known ligand in test samples, or to screen for agonists or antagonists to such ligand, then the ligand binding domain is selected from a known receptor for the ligand. ligand is known, but its receptor is not, then it will be necessary to identify its cell surface receptor. accomplished by 1) securing cells from tissues with which the ligand is known to bind or to functionally interact, 2) obtaining from the cells in known fashion a membrane protein preparation, 3) incubating the preparation with the ligand, 4) separating the ligand-receptor complex from the incubation mixture (for example by preinsolubilizing the ligand on cyanogen bromide activated Sepharose), 5) separating the receptor from the ligand, 6) obtaining amino acid sequence from a portion of the receptor, 7) preparing nucleic acid probes encoding the determined amino acid sequence (either a single long probe of > about 40bp or a pool of shorter probes), 8) preparing a cDNA or genomic DNA phage or plasmid (vector) library from the organism or cells from which the receptor was obtained, 9) hybridizing the probes to the library to identify plasmids or phage which contain DNA encoding the receptor, and 10) determining the nucleotide and imputed amino acid sequence of the receptor to the extent necessary to identify region extending from the amino terminus transmembrane sequence. If no single vector contains DNA encoding the entire extracellular domain of the receptor, the desired DNA is assembled by restriction enzyme digestion of the various 30 vectors at common sites, isolation of the appropriate fragments and relegation by methods already known per se. Other procedures for identifying receptors for known ligands are known to those skilled in the art or will become available in the future.

A putative receptor may have been identified but its ligand in vivo r mains unknown. For example, study of endocrine tissues from such glands as the pituitary or adrenals will lead to the identification of membrane bound proteins that are structurally similar to other known receptors, i.e. they will have a large (typically >500 residues) extracellular domain, a hydrophobic transmembrane sequence and a carboxy-terminal cytoplasmic region. Similarly, a receptor inventory for malignant cells will be useful for identifying unique receptors present in high density that may be associated with the transformed phenotype. The extracellular domains of such receptors are also useful herein.

A receptor and its ligand may have been identified but the cytoplasmic domain may have no known function, e.g. it is not known to have phosphotransferase activity, to activate adenylate or guanylate cyclase, or to transport ligand. The ligand binding domain from such receptors is useful notwithstanding that the ligand-receptor interaction produces no or insufficiently detectable signal in the native receptor because a detectable signal is provided by the reporter polypeptide in the hybrid construction. Thus, in the absence of the reporter polypeptide no method would be available to determine in the case of some receptor whether a receptor-bound candidate drug was binding nonspecifically or was acting as an agonist or antagonist, nor would it be possible to assay for biologically active native ligands.

The reporter polypeptide is heterologous to the ligand binding domain and is any polypeptide that changes its character upon the binding of a ligand to the binding domain. This change in character is generally detected by a change in the enzymatic activity or immunological identity of the reporter polypeptide. Generally the reporter polypeptide will be the cytoplasmic domain of a heterologous receptor or receptor analogue, e.g. oncogene,

35

5

10

15

20

25

which is known to undergo a change in immunological or enzymatic identity upon ligand binding. It is preferred to use the cytoplasmic phosphotransferase from such r ceptors as the insulin or epidermal growth factor receptors. However, other receptors as the B-adrenergic receptor, acetylcholine receptor, adrenaline receptor and the like are known to bind proteins termed G proteins that serve as intermediate transducing molecules in the activation or inhibition of adenylate or granylate cyclases. Such proteins have been isolated and characterized. It is within the scope herein to use as the reporter polypeptide the G protein binding domains of such receptors. It is not necessary to use the entire cytoplasmic domain from a heterologous receptor or receptor analogue, only that portion that performs the desired function herein, nor is it necessary to use a heterologous cytoplasmic domain that is an intact, unmodified sequence from another For example, an amino acid sequence variant or receptor. derivative of the cytoplasmic domain of the receptor supplying the ligand binding domain is also acceptable.

20 Without being limited to a particular theory of function, we believe that the change in the character of the reporter polypeptide is not caused by steric hinderance of the reporter by the ligand, e.g. where the ligand occludes an active site on the reporter domain by virtue of steric bulk. Rather, the 25 method herein harnesses the signal transducing mechanism of receptors whereby changes in the ligand binding domain are transduced through the receptor molecule to the reporter domain by conformational changes in the molecule, which changes affect the function or character of the cytoplasmic domain of the reporter. 30 We have discovered that this transducing mechanism also functions when the reporter polypeptide is heterologous to the ligand

Optionally, the hybrid receptor will contain a transmem-

35

binding domain.

5

10

brane sequence fused between the ligand binding domain and the reporter polypeptide. Typical transmembrane domains contain about from 20 to 25 residues and show a hydropathy peak of about from 1.5 to 3.5. They contain a high proportion of residues having hydrophobic side chains, e.g. leucine, isoleucine, phenylalanine, valine and methionine. Suitable transmembrane sequences are obtained from the receptor supplying the extracellular ligand binding domain, although the transmembrane sequence also may be entirely synthetic or obtained from integral membrane proteins or unrelated receptors, in the last instance including the transmembrane region ordinarily associated with the reporter polypeptide where the reporter is the cytoplasmic domain of a heterologous receptor.

15

20

5

10

The hybrid receptor components suitably originate from humans, animals, plants, insects, microorganisms including parasites, viruses and fungi and other suitable species. The species of origin for the ligand binding domain is selected for the presence of a receptor capable of binding the ligand of interest or for the presence of the target physiological activity. It is not necessary that the reporter polypeptide or transmembrane region be from the same species as the ligand binding domain.

25

The hybrid receptors preferably are synthesized in recombinant cell culture because they are generally too large and complex to practically synthesize by <u>in vitro</u> methods that are available to the art today.

30

Recombinant methods for synthesis of the hybrid receptor commence with the construction of a replicable vector containing nucleic acid that encodes the hybrid receptor. Vectors typically perform two functions in collaboration with compatible host cells. One function is to facilitate the cloning of the nucleic acid that encodes the hybrid receptor, i.e., to produce usable quantities of

the nucleic acid. The oth r function is to direct the expression of the hybrid rec ptor. One or both of these functions are performed by the vector-host system. The victors will contain different components depending upon the function they are to perform as well as the host cell that is selected.

Each vector will contain nucleic acid that encodes the hybrid receptor. Typically, this will be DNA that encodes the hybrid receptor in its mature form linked at its amino terminus to a secretion signal. This secretion signal preferably is the signal presequence that normally directs the secretion of the receptor from which the ligand binding domain was obtained. However, suitable secretion signals also include signals from other receptors or from secreted polypeptides of the same or related species.

The secreted hybrid will lodge in the recombinant host membrane if it contains a transmembrane region. On the other hand, if such a region is not present in the hybrid, then the hybrid may be secreted into the culture medium. hybrids are preferred that contain a transmembrane region so as to retain as much structural fidelity as possible. However, the purification of transmembrane-deleted receptors is less complex than in the case of membrane-bound because in the latter instance the hybrid receptor should be purified free of other cell membrane proteins. Furthermore, the cell-bound hybrid receptor may exert an undesired biological effect on the host if induced to accumulate in large populations in the cell membrane during the This potential problem is overcome by placing the nucleic acid encoding the hybrid receptor under the control of an inducible promoter.

In cloning vectors, the hybrid receptor-encoding nucleic acid ordinarily is present together with a nucleic acid sequence

5

10

15

20

25

30

that enables the vector to replicate in a selected host cell independent of the host chromosomes. This sequence is generally an origin of replication or an autonomously replicating sequence. Such sequences are well-known for a variety of bacteria, yeast and higher eukaryotic cells. The origin from the well-known plasmid pBR322 is suitable for E. coli bacteria, the 2μ plasmid origin for yeast and various viral origins for mammalian cells (SV40, polyoma, adenovirus or bovine papilloma virus). Less desirably. DNA is cloned by insertion into the genome of a host. readily accomplished with bacillus species, for example, by inserting into the vector DNA that is complementary to bacillus genomic DNA. Transfection of bacillus with this vector results in homologous recombination with the genome and insertion of the However, the recovery of genomic DNA hybrid receptor DNA. encoding the hybrid receptor is more complex than obtaining exogenously replicated viral or plasmid DNA because restriction enzyme digestion is required to recover the hybrid receptor DNA from the genome of the cloning vehicle.

20 should contain a Expression and cloning vectors selection gene, also termed a selectable marker. This is a gene that encodes a protein necessary for the survival or growth of a host cell transformed with the vector. The presence of this gene ensures the growth of only those host cells which express the 25 inserts. Typical selection genes encode proteins that (a) confer resistance to antibiotics or other toxins, e.g. ampicillin, neomycin, methotrexate or tetracycline, (b) complement auxotrophic deficiencies, or (c) supply critical nutrients not available from complex media, e.g. the gene encoding D-alanine racemase for 30 bacilli.

A suitable selection gene for use in yeast is the <u>trpl</u> gene present in the yeast plasmid YRp7 (Stinchcomb <u>et al</u>., 1979, "Nature", <u>282</u>: 39; Kingsman <u>et al</u>., 1979, "Gene", <u>7</u>: 141; or

35

5

10

Tschemper et al., 1980, "Gene", 10: 157). The trpl g ne provides a selection marker for a mutant strain of yeast lacking the ability to grow in tryptophan, for example ATCC No. 44076 or PEP4-1 (Jones, 1977, "Genetics", 85: 12). The presence of the trpl lesion in the yeast host cell genome then provides an effective environment for detecting transformation by growth in the absence of tryptophan. Similarly, Leu2 deficient yeast strains (ATCC 20,622 or 38,626) are complemented by known plasmids bearing the Leu2 gene.

10

15

5

Examples of suitable selectable markers for mammalian cells are dihydrofolate reductase (DHFR), thymidine kinase or proteins for neomycin resistance. Such markers enable the identification of cells which were competent to take up the hybrid receptor nucleic acid. The mammalian cell transformants are placed under selection pressure which only the transformants are uniquely adapted to survive by virtue of having taken up the Selection pressure is imposed by culturing the transformants in successive rounds of cell culture in which the concentration of selection agent in the medium is successively increased, thereby leading to amplification of both the selection gene and the DNA encoding the hybrid receptor. quantities of hybrid receptor are synthesized from the amplified DNA.

25

20

For example, selection for DHFR transformed cells is conducted in a culture medium which lacks hypoxanthine, glycine, and thymidine. An appropriate host cell in this case is the Chinese hamster ovary (CHO) cell line deficient in DHFR activity, prepared and propagated as described by Urlaub and Chasin, 1980, "Proc. Nat'l. Acad. Sci. USA" 77: 4216.

30

35

A particularly useful DHFR is a mutant DHFR that is highly resistant to methotrexate (MTX) (EP 117,060A). This

L03x08.mdh

selection agent can be used with any otherwise suitable host, notwithstanding the presence of endogenous DHFR. One simply includes sufficient MTX in the medium to inactivate all of the endogenous DHFR, whereupon MTX selection becomes solely a function of amplification of the mutant DHFR DNA. Most eukaryotic cells which are capable of adsorbing MTX appear to be methotrexate sensitive. One such useful cell line is a CHO line, CHO-K1 (ATCC No. CCL 61).

10

5

Other methods, vectors and host cells suitable for adaptation to the synthesis of the hybrid receptor in recombinant vertebrate cell culture are described in M.J. Gething et al., "Nature" 293: 620-625 (1981); N. Mantei et al., "Nature" 281: 40-46; and A. Levinson et al., EP 117,060A and 117,058A.

15

20

25

30

35

Expression vectors, unlike cloning vectors, contain a promoter and/or other sequence which is recognized by the host organism for strong transcription of the hybrid receptor-This is generally a promoter homologous to the encoding DNA. intended host. In the case of vectors for higher eukaryotes, enhancer sequences are useful for further increasing transcription Unlike promoters, enhancers do not need to be from promoters. located 5' to the hybrid receptor encoding nucleic acid. Commonly used promoters for prokaryotes include the β -lactamase and lactose promoter systems (Chang et al., 1978, "Nature", 275: 615; and Goeddel et al., 1979, "Nature", 281: 544), alkaline phosphatase, a tryptophan (trp) promoter system (Goeddel 1980, "Nucleic Acids Res." 8: 4057 and EPO Appln. Publ. No. 36,776) and hybrid promoters such as the tac promoter (H. de Boer et al., 1983, "Proc. Nat'l. Acad. Sci. USA" <u>80</u>: 21-25). However, other known microbial promoters are suitable. Their nucleotide sequences have been published, thereby enabling a skilled worker operably to ligate them to DNA encoding the hybrid receptor in plasmid vectors (Siebenlist et al., 1980, "Cell" 20: 269) using linkers or

L03x08.mdh

adaptors to supply any required restriction sites. Promoters for use in prokaryotic systems also will contain a Shine-Dalgarno (S.D.) sequence operably linked to the DNA encoding the hybrid receptor.

5

Suitable promoting sequences in yeast vectors include the promoters for metallothionein, 3-phosphoglycerate kinase (-Hitzeman et al., 1980, "J. Biol. Chem.", 255: 2073) or other glycolytic enzymes (Hess et al., 1968, "J. Adv. Enzyme Reg.", 7: 149; and Holland, 1978, "Biochemistry", 17: 4900), such as enolase, glyceraldehyde-3-phosphate dehydrogenase, hexokinase, pyruvate decarboxylase, phosphofructokinase, glucose-6-phosphate isomerase, 3-phosphoglycerate mutase, pyruvate kinase, triose-phosphate isomerase, phosphoglucose isomerase, and glucokinase.

15

10

Other yeast promoters, which have the additional advantage of transcription controlled by growth conditions, are the promoter regions for alcohol dehydrogenase 2, isocytochrome C, acid phosphatase, degradative enzymes associated with nitrogen metabolism, and the aforementioned metallothionein and glyceraldehyde-3-phosphate dehydrogenase, as well as enzymes responsible for maltose and galactose utilization. Suitable vectors and promoters for use in yeast expression are further described in R. Hitzeman et al., EP 73,657A.

25

30

20

Transcription from vectors in mammalian host cells is controlled by promoters and/or enhancers obtained from the genomes of bovine papilloma virus, vaccinia virus, polyoma virus, adenovirus 2, retroviruses, hepatitis-B virus and most preferably Simian Virus 40 (SV40), operably linked to the hybrid receptor nucleic acid. The early and late promoters of the SV40 virus are as conveniently obtained as an SV40 restriction fragment which also contains the SV40 viral origin of replication (Fiers et al., 1978, "Nature", 273: 113). Of course, promoters or enhancers from

th host cell or related species also are useful herein.

Nucleic acid is operably linked when it is placed into a functional relationship with another nucleic acid sequence. For example, DNA for a presequence or secretory leader is operably linked to DNA for a polypeptide if it is expressed as a preprotein which participates in the secretion of the polypeptide; a promoter or enhancer is operably linked to a coding sequence if it affects the transcription of the sequence; or a ribosome binding site is operably linked to a coding sequence if it is positioned so as to facilitate translation. Generally, operably linked means that the DNA sequences being linked are contiguous and, in the case of secretory leader, contiguous and in reading frame.

15

20

5

10

Expression vectors used in eukaryotic host cells (yeast, fungi, insect, plant, animal or human) will also contain sequences necessary for the termination of transcription and for stabilizing the mRNA. Such sequences are commonly available from the 3' untranslated regions of eukaryotic or viral cDNAs. These regions contain regions that are transcribed as polyadenylated segments in the untranslated portion of the mRNA encoding the hybrid receptor. The 3' untranslated regions also include transcription termination sites.

25

Suitable host cells for cloning or expressing the vectors herein are prokaryotes, yeast or higher eukaryotic cells. Prokaryotes include gram negative or gram positive organisms, for example <u>E. coli</u> or bacilli. A preferred cloning host is <u>E. coli</u> 294 (ATCC 31,446) although other gram negative or gram positive prokaryotes such as <u>E. coli</u> B, <u>E. coli</u> X1776 (ATCC 31,537), <u>E. coli</u> W3110 (ATCC 27,325), pseudomonas species, or <u>Serratia Marcesans</u> are suitable.

35

30

In addition to prokaryotes, eukaryotic microbes such as

filamentous fungi or yeast are suitabl hosts for the hybrid receptor encoding vectors. <u>Saccharomyces c revisiae</u>, r common baker's yeast, is the most commonly us d among lower eukaryotic host microorganisms. However, a number of other genera, species and strains are commonly available and useful herein.

preferred host cells for the expression of functional hybrid receptors are cultures of cells derived from multicellular organisms. In many cases, hybrid receptors contain hydrophobic regions that are incompatible with lower microorganisms, require complex processing to properly form disulfide bonds and often require subunit processing. In addition, it is desirable to glycosylate the receptors in a fashion similar to the native receptors. All of these functions can be best performed by higher eukaryotic cells. In principle, any higher eukaryotic cell culture is workable, whether from vertebrate or invertebrate culture, although cells from mammals such as humans are preferred. Propagation of such cells in culture is per se well known. Tissue Culture, Academic Press, Kruse and Patterson, editors (1973). Examples of useful mammalian host cell lines are VERO and HeLa cells, Chinese hamster ovary cell lines, and WI38, BHK, COS-7 and MDCK cell lines.

The hybrid receptors of this invention are employed in drug screening or biologically active ligand assay by a process that fundamentally comprises incubating the receptor with the test sample, controls and (optionally) standards, followed by measuring change in the reporter polypeptide. Since we have discovered that ligand binding causes a change in the conformation of the reporter polypeptide it is within the scope hereof to detect such changes by any one of several methods. Typically, one measures changes in the protein binding or enzymatic activity of the reporter polypeptide. In one embodiment an antibody is raised against the activated conformation and the binding of this

5

10

15

20

25

antibody to th hybrid receptor is measured after the receptor has been incubated with the ligand or candidate drug. This assay is conducted in the same fashion as conventional immunoassay meth ds for any protein antigen. Antibodies are known per s that are capable of binding phosphotyrosine containing proteins (Wang, 1985, "Mol. and Cell. Biol." 5(12): 3640-3643; Ross et al., 1981. "Nature" 294: 654; and Pang et al., 1985, "Arch. Biochem. Biophys. " 242(1): 176). While those antibodies are useful in the method herein, hybrid receptors enable the selection of antiphosphotyrosine antibodies that, unlike the prior art antibodies, are specific for the reporter polypeptide and will not cross-react with other receptors or phosphorylated proteins, yet which are just as versatile in measuring the effect of a ligand on a receptor binding domain. The disadvantage of this method is that it requires a phase separation to remove the unbound labelled antibody from the reporter-bound antibody. However, the method does not require covalent modification of the hybrid receptor.

Analogous to assays using the binding of a specific antibody to the reporter polypeptide are methods that directly or indirectly measure the binding to the reporter of a non-immune binding protein with which it normally interacts. Typical binding proteins are the G proteins that associate with certain ligand-activated receptors. The reporter polypeptide in this case is the cytoplasmic domain of a receptor such as the beta-adrenergic receptor. The binding of the G protein is assayed in the same fashion as antibody binding, e.g. by displacement of labelled G protein, or by determination of GTP or ATP binding to the activated G protein.

If the reporter polypeptide is the enzymatically active cytoplasmic domain of a heterologous receptor, then the preferred detection method will be an assay for that activity. At the present time such activity includes protein phosphorylkinase

LO3x08.mdh

5

10

15

20

25

30

activity, primarily tyrosine kinase activity but in some cases serine or threonine kinase activity. Kinase activity is measurabl in any way in which kinase activity has be n assayed heretofore. One convintional, and presently preferred, method for kinase activity is to assay the incorporation of radiophosphorus into the reporter polypeptide through autophosphorylation with ³²P. It is preferred to form hybrids of receptors having the same class of activity.

10

15

20

25

30

5

However, it is within the scope herein to measure changes in the reporter polypeptide by methods other than enzymological activity or polypeptide interactions. method contemplates binding an organic moiety to the receptor that undergoes a change in character upon ligand binding. For example, the reporter polypeptide is labelled with a stable free radical, a chemiluminescent group or a fluorescent molecule such as fluorescein isothiocyanate. Each of these labels are well known in the diagnostic immunochemistry art and conventional methods are well known for covalently linking them to proteins. These methods are useful for labelling the reporter polypeptide in the same fashion as other proteins. Changes in the conformation of the receptor polypeptide upon the binding of ligand or active candidate drug to the ligand binding domain are detected by changes in the label. For example, the rotational moment of a stable free radical label will be increased or decreased by ligand-activated changes in reporter polypeptide conformation. Similarly, the fluorescence or luminescence of reporter polypeptide labels will change upon the binding of ligand or active candidate to the receptor because of the reorientation of polypeptide species that engage in intramolecular energy transfers. This is detected by changes in the intensity, polarization or wave length of the label molecule; typically, one detects enhancement, or quenching of the label fluorescence or chemilumin-The advantage of the labelled reporter method is that

the ligand or candidate drug assay is conducted exclusively in aqueous solution and no phase separation is required. This permits the automation of the screening method using continuous flow instruments such as Aut analyzers. Such methods are useful with native as well as the hybrid receptors.

In order to simplify the Examples certain frequently occurring methods will be referenced by shorthand phrases.

10

5

"Plasmids" are designated by a low case p preceded and/or followed by capital letters and/or numbers. The starting plasmids herein are commercially available, are publicly available on an unrestricted basis, or can be constructed from such available plasmids in accord with published procedures. In addition, other equivalent plasmids are known in the art and will be apparent to the ordinary artisan.

20

25

15

"Digestion" or "cleavage" of DNA refers to catalytic cleavage of the DNA with an enzyme that acts only at certain locations in the DNA. Such enzymes are called restriction enzymes, and the sites for which each is specific is called a restriction site. The various restriction enzymes used herein are commercially available and their reaction conditions, cofactors and other requirements as established by the enzyme suppliers were enzymes commonly are designated used. Restriction abbreviations composed of a capital letter followed by other letters representing the microorganism from which each restriction enzyme originally was obtained and then a number designating the particular enzyme. Appropriate buffers and substrate amounts for particular restriction enzymes are specified by the manufacturer. Incubation times of about 1 to several hours at 37°C are ordinarily used, but may vary in accordance with the supplier's instructions. After incubation, protein is removed by extraction with phenol and chloroform, and the digested nucleic acid is

30

recovered from the aqueous fraction by precipitation with ethanol. Digestion with a r striction enzyme infrequently is followed with bacterial alkaline phosphatase hydrolysis of the terminal 5' phosphates to prevent the two restriction cleaved ends of a DNA fragment from "circularizing" or forming a closed loop that would impede insertion of another DNA fragment at the restriction site. Unless otherwise stated, digestion of plasmids is not followed by 5' terminal dephosphorylation. Procedures and reagents for dephosphorylation are conventional (T. Maniatis et al., 1982, Molecular Cloning pp. 133-134).

"Filling" or "blunting" refers to the procedure by which the single stranded end in the cohesive terminus of a restriction enzyme-cleaved nucleic acid is converted to a double strand. eliminates the cohesive terminus and forms a blunt end. process is a versatile tool for converting a restriction cut end that may be cohesive with the ends created by only one or a few other restriction enzymes into a terminus compatible with any blunt-cutting restriction endonuclease or other filled cohesive Typically, blunting is accomplished by incubating 2- $15\mu g$ of the target DNA in 10mM Mg Cl₂, 1mM dithiothreitol, 50mM NaCl, 10mM Tris (pH 7.5) buffer at about 37°C in the presence of 8 units of the Klenow fragment of DNA polymerase I and 250 µM of each of the four deoxynucleoside triphosphates. The incubation generally is terminated after 30 min. by phenol and chloroform extraction and ethanol precipitation.

"Recovery" or "isolation" of a given fragment of DNA from a restriction digest means separation of the digest on polyacrylamide or agarose gel by electrophoresis, identification of the fragment of interest by comparison of its mobility versus that of marker DNA fragments of known molecular weight, removal of the gel section containing the desired fragment, and separation of the DNA from the gel. This procedure is known generally. For

5

10

15

30

example, see R. Lawn et al., 1981, "Nucleic Acids Res." 9:6103-6114, and D. Goeddel et al., 1980, "Nucleic Acids Res.: 8:4057.

"Transformation" means introducing DNA into an organism so that the DNA is replicable, either as an extrachromosomal element or chromosomal integrant. Unless otherwise provided, the method used herein for transformation of <u>E. coli</u> is the CaCl₂ method of Mandel et al., 1970, "J. Mol. Biol." <u>53</u>: 154.

This state of the process of forming phosphodiester bonds between two double stranded nucleic acid fragments (T. Maniatis et al., Id., p. 146). Unless otherwise provided, ligation may be accomplished using known buffers and conditions with 10 units of T4 DNA ligase ("ligase") per 1 μg of the DNA fragments to be ligated.

"Preparation" of DNA from transformants means isolating plasmid DNA from microbial culture. Unless otherwise provided, the alkaline/SDS method of Maniatis et al., Id., P. 90, may be used.

"Oligonucleotides" are short length single or double stranded polydeoxynucleotides which are chemically synthesized by known methods and then purified on polyacrylamide gels.

The following examples are intended to merely illustrate the best mode now known for practicing the invention, but the invention is not to be considered limited thereto.

All literature citations herein are expressly incorporated by reference.

Example 1

Construction of the Insulin Receptor (IR) Expression Plasmid

5

10

15

20

A gel purified SalI fragment (5.2 kb) from \(\lambda\)HIR-P12 containing the entire HIR coding sequence was subcloned into the pUC12 (New England Biolabs) polylinker region by digesting pUC12 with SalI and ligating the purified SalI fragment to the vector. Colonies were grown up and screened for clones having the desired orientation with the 5' end of the HIR coding sequence next to the pUC12 XbaI site. This vector was cut with XbaI and DraI (DraI is located in the 3' untranslated region of HIR) and the HIRcontaining fragment was isolated. This fragment was inserted into a mammalian expression vector (pCVSVEHBVE400, European Publn. No. 117,060), which had been digested first with BamHI. cohesive terminii were filled and the plasmid then was digested with XbaI. Thus, insertion of the XbaI-DraI was only possible in the orientation necessary for expression of the HIR mRNA. resulting insulin receptor expression plasmid was designated pCVSV-HIRc.

Example 2

Construction of a Vector for Expression of an Insulin-EGF Receptor Hybrid

30

25

The following fragments were ligated in a four-factor ligation: (a) A 931 bp <u>Bam</u>HI-<u>Aat</u>II restriction fragment from the IR expression plasmid pCVSVE-HIRC, (b) a 1150 bp <u>ApaI-SstI</u> restriction fragment of the human EGF receptor sequence contained in the recombinant phage λHER-A64 (Ullrich <u>et al.</u>, 1984, "Nature" <u>309</u>: 418-425), (c) a synthetic oligonucleotide linker containing 5'-CCCGTCAAATATCGCCACTGGGATGGTGGGGGCC-3' and 5'-CCCACCATCCCAGTGGC GATATTTGACGGGACGT-3', and (d) pUC12 opened with <u>SstI</u> and <u>Bam</u>HI.

In this way sequences coding for the extracellular domain of the insulin receptor were joined to sequences coding for the transmembrane and cytoplasmic domains of the EGF r ceptor and placed into an expression plasmid. Plasmid pUC12/HIR-HER Int. which contained DNA encoding the hybrid was recovered from an ampicillin resistant colony of transformant E. coli 294. plasmid was digested with BamHI and ApaI and a 965bp fragment containing the IER junction was recovered (fragment 1). HIRc was digested with PvuI and BamHI and a 3117 bp fragment containing the rest of the IR coding sequence and parts of the mammalian expression vector was recovered (fragment 2). is digested with ApaI-BglII and an 810 bp fragment recovered (fragment 3) and with BglII-XmnI and a l kb fragment recovered (fragment 4). Fragments 3 and 4 code for the transmembrane and cytoplasmic domains of the human EGF receptor. pCVSVEHBVE400 is digested with BamHI, the restriction site was endfilled and the DNA subsequently digested with PvuI. A 4 kb BamHI-PvuI fragment was recovered (fragment 5) coding for parts of the mammalian expression vector as described. A mixture of fragments 1, 2, 3, 4 and 5 was ligated and used to transform E. coli 294 DNA. Ampicillin resistant colonies were screened by restriction analysis. A 241 bp Pst I fragment overlapping the HIR-HER junction was cloned into M13Ty131 and sequenced to verify the expected junction.

25

30

20

5

10

15

An expression vector for a hybrid receptor not containing a transmembrane region is constructed in the same fashion as described above using pCVSV-HIRc except that the transmembrane region downstream from the ApaI EGF receptor is deleted by M13 mutagenesis and an in-frame ApaI adaptor ligated to the deleted ER fragment.

A vector encoding the hybrid receptor I α ER, a hybrid of the insulin receptor α chain with the EGF receptor transmembrane

and cytoplasmic domains without any HIR B-chain sequence, was made by oligonucleotide-directed del tion mutagenesis of th plasmid. A 2.1 kb BglII restriction fragment coding for joined insulin and EGF receptor sequences was introduced into the BamHI site of an M13mp10 v ctor. Molecules with the desired orientation of the IR sequences next to the HindIII site of M13mp10 were identified and a single-stranded template was prepared deletion mutagenesis with the oligonucleotide 5'-CCCCAGGCCATCTATCGCCACTGGGA-3' based on the protocols of Adelman et al. "DNA" 2: 183-193 (1983). 50 ng of phosphorylated primer was hybridized to 2 μ g of single-stranded M13 template. mutagenized second strand was completed and double-stranded molecules were introduced into E. coli JM101. Resulting plaques were screened as described by Benton and Davis "Science" 196: 180-182 (1977) at high stringency using the primer as a hybridization Double-stranded DNA was prepared and a 1.2 kb BstEII restriction fragment containing the mutated region was used to replace the respective DNA fragment in the IER expression plasmid, yielding plaER.

Example 3

Expression of the Hybrid Insulin and EGF Receptors

COS-7 monkey kidney cells (Gluzman, 1981, "Cell" 23: 175-182) were cultured in DMEM mixed with F12 medium (50:50), containing 10 percent fetal bovine serum and antibiotics. All cell culture media (Gibco) contained 2mM L-glutamine and 20mM HEPES pH 7.4.

30

pIER or pI α ER from Example 2 was introduced into COS-7 cells by calcium phosphate coprecipitation based on the protocol of Graham and Van der Eb, 1973, "Virology" <u>52</u>: 456-467. Subconfluent cells were transfected with 10 μ g of plasmid DNA per 8 cm culture dish. Plasmid DNA was dissolved in 0.55 ml of 1mM

Tris pH 7.5, 0.1mM EDTA, 250mM CaCl₂, after which 0.5 ml of 50mM HEPES pH 7.12, 280mM NaCl and 1.5mM Na₂HPO₄ was slowly added. A precipitate gradually formed within 45 min. which was added to the cell culture medium. The transfected COS-7 cells were cultured for 53 hrs. at 37°C in DMEM mixed with F-12 medium (50:50) containing antibiotics, 2mM L-glutamine, 20 mM HEPES and 10% by volume fetal bovine serum (pH 7.4).

COS-7 cells transformed with pIER or pI α ER were washed two times with PBS and incubated in 1 ml of serum-free cell culture medium per 2.2 cm well containing 0.2% bovine serum albumin (Sigma), bacitracin (0.5 mg/ml, Sigma) and 125 I insulin (0.5 μ Ci/well) at 93 μ Ci/ μ g for 2 h at 21°C. Cells were washed 3 times with PBS at 4°C and lysed in 0.5 ml 0.1 percent SDS, 0.1 M NaOH for 30 min. at 37°C. The radioactivity was determined in a gamma counter. Fig. 2a demonstrates that insulin binding to the transformants increased over that of controls.

Human epidermoid carcinoma cells A431 (a source of EGF receptor controls) were cultured in DMEM containing 4.5 mg glucose per liter, 10 percent fetal bovine serum and antibiotics.

Example 4 Hormone Stimulated Autophosphorylation of Normal and Hybrid Receptors

pIER or pIaER transformed and mock transformed COS-7 cell monolayers grown in 8 cm culture dishes for 53 hours, or A431 cells, were washed twice with PBS and solubilized as described by

Kris et al., 1985, "Cell" $\underline{40}$: 619-625. One ml of 50mM HEPES buffer pH 7.5 containing 150mM NaCl, 1.5mM MgCl₂, 1mM EGTA, 10 percent glycerol, 1 percent Triton X-100, 1 percent Aprotinin (Sigma) and $4\mu g/ml$ phenylmethylsulfonyl fluoride (PMSF) (Sigma) and 0.5 mg/ml bacitracin (Sigma) was added to the monolayers at

5

10

15

20

25

 4°C for 5 min. The buffer which contained the solubilized cellular proteins was removed from the culture dish and centrifuged at 10,000g for 5 min at 4°C . Culture supernatants from transmembrane-d leted hybrid receptor transformed cells are centrifuged at 10,000 g for 5 min. at 4°C . 0.2 ml of the cell lysis or culture supernatant was incubated with 200nM insulin (Sigma) or $1~\mu\text{M}$ EGF for 1 hour.

A mouse monoclonal antibody capable of binding the insulin receptor (CII25.3, described by Ganguly et al., 1985, "Current Topics in Cellular Regulation" 27: 83-94) was insolubilized by adsorption to protein A-Sepharose. However, it will be appreciated that any polyclonal or monoclonal anti-insulin receptor antibody can be used. 1μl of antibody was mixed with 50 μl of a swollen and prewashed 1:1 protein A-Sepharose slurry in detergent-free lysis buffer for 30 min in order to adsorb the anti-IR antibody.

 $_{\rm c}$ 50 μ l of insolubilized anti-IR antibody slurry was added to the EGF or insulin treated cell lysate or cell culture supernatant and incubated for 15 min. at 4°C. The resulting immunoprecipitate was washed 4 times with 0.9 ml HNTG buffer (20mM HEPES pH 7.5, 150mM NaCl, 10 percent glycerol, and 0.1 percent Triton X-100). The precipitate in a volume of 30 μ l was adjusted to 5mM MnCl₂, and 15 μ Ci of γ -32P-ATP (5,000 Ci/mmol) was added for 0.5-10 min. at 4°C. The final ATP concentration was 0.1 pM ATP (for EGF, IER or IαER transformants and their controls) or 100 μM HIR transformants and their controls). autophosphorylation reaction was stopped by adding 20 μ l of 3 times concentrated SDS sample buffer. The autophosphorylation reaction was terminated after 5 min. in Fig. 3a and 3d, 1 min. in Fig. 3b and after the times indicated in Fig. 3c by boiling for 5 The samples were centrifuged were and 20 μ l aliquots analyzed on 5 percent/7 percent SDS polyacrylamide gels (Laemmli,

5

20

25

30

The patterns obtained on SDS-PAGE reducing gels matched the 35S-Met labeling result for those polypeptides that contain tyrosine kinase sequences. Figure 3b (HIR+) shows the insulinstimulated autophosphorylation of the human insulin receptor $oldsymbol{eta}$ subunit above the endogenous COS-7 control. In this case the insulin induction effect is strong, although the visualized signal is weak due to the ATP concentration (100 μ M) required by the insulin receptor kinase. In contrast, only picomolar concentrations are needed to measure EGF receptor kinase activity and EGF stimulation, as shown in the A431 cell EGF receptor control (A431). The characteristics of the chimeric receptor molecule IER reflects the presence of the EGF receptor kinase because of the low ATP concentrations required. Since ligand induction increases the Vmax of the kinase, maximal induction (4 fold) is observed in a 30 second reaction at 4°C (Figure 3c). This finding is in good correlation with the kinetic properties of the wild type EGF receptor (Staros et al., 1985, in Molecular Aspects of Cellular Regulation Vol.4: Molecular Mechanisms of Transmembrane Signaling) and indicates that the EGF receptor kinase retains its original characteristics when controlled by the insulin binding domain.

Surprisingly, the insulin-stimulated and unstimulated 130 kd phosphoprotein subunits of the IE receptor hybrid display a subtle but reproducible size difference (Figure 3d). This observation raises the possibility that ligand-induced enzymatic activity leads to phosphorylation of tyrosine residues not modified at basal levels; a subsequent conformational change of the cytoplasmic receptor domain could alter migration characteristics in SDS gels. A similar change may occur in the intact EGF receptor but has not been detected due to the larger size of the monomeric 170 kd glycoprotein. Electrophoretic migration changes have been reported for other autophosphorylated proteins

5

10

15

20

25

such as Ca²₊/Calmodulin-dependent protein kinase (Kuret <u>et al.</u>, 1985, "J. Biol. Chem." <u>260</u>:6427-6433), type II cAMP-dependent protein kinase (Hemmings <u>et al.</u>, 1981, "Eur. J. Biochem." <u>119</u>:443-451).

5

10

15

Since uncleaved chimeric proreceptor IER displays insulinstimulated autophosphorylation (Fig. 3b and 3c, IER + gel, top band), the tertiary structure necessary for insulin binding and signal transduction must be formed prior to insulin receptor proteolytic processing, consistent with previous (Blackshear et al., 1983, "FEBS" 158:243-246; Rees-Jones et al., 1983, "Biochem. Biophys. Res. Comm. 116:417-422). Our experiments with the chimeric construct IoER, in which the extracellular portion of the insulin receptor β subunit and the proreceptor cleavage site are deleted, (Fig. 3b, $I\alpha ER$ compare + and -) indicate that despite the apparent ability of the resulting 180 kd single-chain glycoprotein to bind insulin, insulin activation of the cytoplasmic kinase domain is lost.

20

25

30

As shown above, insulin regulates the rate of the EGF autophosphorylation activity at subpicomolar receptor concentrations of ATP, conditions under which the phosphotransferase of the insulin receptor is inactive. Hormone control was only observed for the hybrid IER containing the complete extracellular portion of the insulin receptor, including the signal for receptor processing into the α and β subunits and the amino terminus of the β subunit. The receptor appears to be processed in our expression system. In the case of the chimera In ER lacking any portions of the eta subunit and consequently the cleavage signal, no hormone effect was observed. We conclude that this structural difference between IER and IaER has a profound effect on the structure of the chimeric receptor that is crucial for signal transduction.

Example 5

Construction of a Vector Encoding a Receptor-Oncogene Hybrid (HER-erbB)

We constructed a hybrid receptor comprised of the intracellular domain of the <u>v-erbB</u> oncogene product fused to the extracellular and transmembrane domains of the EGF receptor (HER-erbB; Fig. 4).

The hybrid receptor is expressed from a plasmid under the control of the early promoter of SV40. This plasmid also contains a mutant DHFR gene for methotrexate (MTX) resistance. Selection is accomplished by cotransformation with a plasmid encoding a neomycin resistance gene and the DNA amplified by selection in MTX-containing culture media.

AHER-A64 (Ullrich et al.) was digested with SacI and NarI and a restriction fragment coding for the complete extracellular and transmembrane domain of the EGF receptor was recovered. A 1.7 kb AhaII-StuI restriction fragment coding for the complete intracellular portion of AEV-erbB (H) (Yamamoto, T. et al., 1983 "Cell" 35:71-78) was ligated together with the EGF fragment into a pUCl2 plasmid opened with SacI and SmaI. The recombinant plasmid was amplified in E. coli HB101 and the coding region for the complete chimeric receptor is removed in a 3.7 kb SacI-XmnI restriction fragment, both sites being located in the untranslated regions of the EGF receptor and v-erbB sequence, respectively.

p342E (Crowley et al., 1983, "Mol. Cell. Biol." 3:44-55)

was digested with <u>Eco</u>RI and the opened plasmid recovered. An adaptor having the sequence

EcoRI SacI EcoRI
GAATTCGAGCTC
CTCGAGCTTAAG

is light d with the opened plasmid, the lightion mixture transfected into \underline{E} , \underline{coli} 294, and plasmid pCVSVE-HBS having the adaptor insert is recovered from an ampicillin resistant colony.

5

pCVSVE-HBS is partially digested with <u>SacI</u> and the linearized vector fragment (I) recovered. The linearized plasmid is digested with <u>HpaI</u> and the vector fragment recovered.

10

The pCVSVE-HBS vector fragment is ligated to the <u>SacI-XmnI</u> fragment encoding the hybrid receptor and expression vector pCVSV-HER-erbB was recovered from a transformed <u>E. coli</u> HB101 colony.

15

20

25

Example 6 Expression of Receptor-Oncogene Hybrid

Expression vector pCVSVE-HER-erbB is cotransfected into normal Rat 1 fibroblasts together with a neomycin resistable expression plasmid by calcium phosphate coprecipitation based on the protocol of Graham and van der Eb (1973). Subconfluent cells were transfected with 10 μ g of plasmid DNA per 8 cm culture dish. DNA was dissolved in 0.55 ml of 1mM Tris pH 7.5, 0.1mM EDTA, 250mM Cacl₂ and 0.5 ml of 50mM HEPES pH 7.12, 280mM NaCl, 1.5mM Na₂HPO₄ was slowly added. A precipitate gradually formed within 40 min. which was added to the 10 ml of cell culture medium. 5h after transfection, cells were subjected to a glycerol shock treatment by incubation in 3 ml of 20 percent glycerol in PBS for 1 min. The glycerol was washed off and the cells were further cultured in the original medium.

The neomycin resistance gene under the control of the SV40 early promoter was used as a selectable marker. Medium supplemented with 400 $\mu g/ml$ Geneticin (Sigma G5013) was used for

35

selection starting two days after transfection. Neomycin-resistant cells were then grown in medium supplemented with a 200 nM, then 1000 nM conc ntration of methotrexate (Sigma A6770) containing 7 percent dialyzed fetal bovine serum. The r sult was a step-wise amplification of cDNA expression in neomycin resistant cell lines.

Expression of the hybrid in the transformants was first monitored by analyzing proteins metabolically labeled with 35smethionine after immunoprecipitation of detergent lysates with a human EGF receptor-specific mouse monoclonal antibody R1. expressing cell lines were metabolically labelled with 35s. Specific proteins were immunoprecipitated by protein A-Sepharose adsorbed R1 antibody from detergent lysates prepared as described above and analyzed on SDS reducing polyacrylamide gels. The mouse monoclonal Rl antibody (Waterfield et al., 1982, "J.Cell.Biochem." 20:149-161) does not recognize the endogenous RatI cell EGF receptor. The HER-erbB protein was readily detected in immunoprecipitates before and after methotrexate amplification. As expected, the HER-erbB protein was smaller than the wild type EGF receptor expressed in A431 cells. When compared with the very high level of EGF receptor expressed in A431 cells, amplified RatI cells expressed only 3-fold less HER-erbB.

The hybrid HER-<u>erbB</u> protein displayed specific EGF binding since ¹²⁵I-EGF at various concentrations was bound to transformant cells. The binding was saturable and could be completely displaced in the presence of a 100-fold excess of unlabelled EGF. The amount of binding of ¹²⁵I-labeled EGF to confluent RatI cultures corresponded precisely to the amount of EGF receptor or chimeric receptor expressed by the respective cell cultures. Thus the constructed proteins contained fully functional EGF binding domains and were faithfully transported to the cell surface.

5

10

15

20

25

Example 7 EGF-stimulated in vitro autophosphorylation

To test whether HER-erbB possessed in vitro autophosphory-lation activity, cell lysates were immunoprecipitated as described above, incubated with $^{32}\text{P-}\gamma\text{-ATP}$ and analyzed by polyacrylamide gel electrophoresis and autoradiography: Transformant cell monolayers grown in 8 cm culture dishes were washed twice with PBS and solubilized as described by Kris et al. "Cell" $^{40:619-625}$ (1985). One ml of 50 mM HEPES pH 7.5, 150mM NaCl, 1.5mM MgCl₂, 1mM EGTA, 10 percent glycerol, 1 percent Triton X-100, 1 percent Aprotinin and $^{4\mu\text{g}/\text{ml}}$ phenylmethylsulfonyl fluoride (PMSF) was added to the monolayers at 4°C for 5 min. Solubilized cells were centrifuged at 10,000g for 5 min at 4°C, and the supernatant was either stored at -70°C or processed further.

EGF stimulation of autophosphorylation was induced by incubating the detergent cell lysates diluted to a 0.5 percent TX-100 concentration in 0.4 ml prior to the immunoprecipitation, with 5 μ g/ml EGF for 15 min at 4°C. Rl antibody prebound for 30 min to protein A-Sepharose was added (1 µl antibody/50 µl slurry 1:1), and the incubation continued for 15 min at 4°C. immunoprecipitates were washed 5 times in 0.9 ml HNTG buffer (20mM HEPES pH 7.5, 150mM NaCl, 10 percent glycerol, and 0.1 percent Triton X-100). The washed immunoprecipitates, in a volume of 30 μ l, were adjusted to 5mM MnCl₂ and 15 μ Ci of γ -32P-ATP was added for 0.5 min at 4°C. The autophosphorylation reaction was stopped by adding 20 μ l of 3 times concentrated SDS sample buffer. Samples were boiled for 5 min, centrifuged, and 20 μ l aliquots analyzed on 5 percent/7 percent SDS polyacrylamide reducing gels (Laemmli, 1970). Gels were fixed and dried under vacuum at 70°C. Normal RatI fibroblasts were used as a control. Size markers are indicated in kilodaltons. Like the wild type EGF receptor, the HER-erbB hybrid incorporated significant amounts of 32p in

5

10

15

20

25

30

immunoprecipitates. The extent of phosphorylation was increased by the addition of EGF (designated by +); when measured at 30 seconds, the rate of phosphorylation was found to be 3 fold higher in the presence of EGF. The v-erbB protein itself possesses only very low autophosphorylation activity (Lax et al., 1985, "EMBO Journal" 4:3179-3182). Despite the low autophosphorylation activity claimed in the hybrid, reconstitution of the EGF binding domain led to ligand-inducible autophosphorylation activity.

CLAIMS

- 1. A hybrid receptor comprising (a) the ligand binding domain of a predetermined receptor and (b) a heterologous 5 reporter polypeptide.
 - 2. The hybrid receptor of claim 1 wherein the ligand binding domain is comprised by the extracellular domain of the predetermined receptor.

- 3. The hybrid receptor of claim 1 wherein the reporter polypeptide is a cytoplasmic domain of a receptor or oncogene.
- 15 4. The hybrid receptor of claim 1 wherein the reporter polypeptide is an enzyme.
- 5. The hybrid receptor of claim 4 wherein the enzyme is not sterically inhibited by the binding of a ligand to the 20 hybrid receptor.
 - 6. The hybrid receptor of claim 4 wherein the enzyme is a phosphorylkinase.
- 25 7. The hybrid receptor of claim 1 having a transmembrane domain interposed between the ligand binding domain and the heterologous reporter polypeptide.
- 8. Nucleic acid encoding a hybrid receptor comprising (a) 30 the ligand binding domain of a predetermined receptor and (b) a heterologous reporter polypeptide.
 - 9. The nucleic acid of claim 8 further comprising a replicable vector.

- 10. The vector of claim 9 further comprising a host cell.
- 11. A method for making a hybrid receptor which receptor comprises (1) the ligand binding domain of a predetermined receptor and (2) a heterologous reporter polypeptide, said method comprising:
- (a) transforming a host cell with a vector containing nucleic acid encoding the hybrid receptor operably linked to a promoter for controlling the transcription of the hybrid receptor; and
- (b) culturing the host cell under conditions for expressing the hybrid receptor.
- 12. The method of claim 11 wherein the hybrid receptor is recovered from the culture medium of the host cell.
 - 13. The method of claim 11 wherein the hybrid receptor is recovered from the cell membrane of the host cell.
- $_{20}$ 14. A method for assaying a biologically active ligand or an antagonist or agonist for said ligand, comprising:
 - (a) providing a hybrid receptor which comprises (1) a binding domain for the ligand, antagonist or agonist and (2) a heterologous reporter polypeptide;
- 25 (b) incubating the receptor with a test sample suspected to contain the ligand, antagonist or agonist;
 - (c) detecting a change in the reporter polypeptide; and
- (d) correlating said change with the presence of the $_{30}$ ligand, antagonist or agonist in the test sample.
 - 15. The method of claim 14 wherein the ligand is a polypeptide and the ligand binding domain is not the antigen binding site of an immunoglobulin.

- 16. The method of claim 14 wherein the change in the reporter polypeptide is a modification of the enzymatic activity of the polypeptide.
- 5 17. The method of claim 16 wherein the change in the reporter polypeptide is autophosphorylation of the reporter polypeptide.
- 18. The method of claim 14 wherein the test sample is 10 suspected to contain an antagonist and the receptor is incubated with the test sample and a predetermined activity of ligand or ligand agonist.
- 19. The method of claim 14 wherein the change in the 15 reporter polypeptide is a change in an immune epitope.
- 20. The method of claim 19 wherein the change in immune epitope is detected by incubating the receptor with an antibody capable of binding to the reporter polypeptide and determining the amount of bound or residual unbound polypeptide.
- 21. The method of claim 14 wherein the reporter polypeptide further comprises a stable free radical, fluorescent or chemiluminescent group and the change in the reporter polypeptide is detected by measuring a change in the rotational moment of the stable free radical or a change in the intensity, wavelength or polarization of the fluorescent or chemiluminescent group.

30

22. The method of claim 14 wherein the reporter polypeptide is capable of binding to a G protein.

CLAIMS

- 1. A process which comprises the preparation of a hybrid receptor comprising (a) the ligand binding domain of a predetermined receptor and (b) a heterologous reporter polypeptide.
- The process of claim 1 wherein the ligand binding domain is comprised by the extracellular domain of the 10 predetermined receptor.
 - 3. The process of claim 1 wherein the reporter polypeptide is a cytoplasmic domain of a receptor or oncogene.
- 15 4. The process of claim 1 wherein the reporter polypeptide is an enzyme.
- 5. The process of claim 4 wherein the enzyme is not sterically inhibited by the binding of a ligand to the 20 hybrid receptor.
 - 6. The process of claim 4 wherein the enzyme is a phosphorylkinase.
- 7. The process of claim 1 wherein the hybrid receptor has a transmembrane domain interposed between the ligand binding domain and the heterologous reporter polypeptide.
- 8. A process which comprises the preparation of nucleic 30 acid encoding a hybrid receptor comprising (a) the ligand binding domain of a predetermined receptor and (b) a heterologous reporter polypeptide.
 - 9. The process of claim 8 wherein the nucleic acid further —

comprises a replicable vector.

10. The process of claim 9 which further comprises transforming a host cell with the vector.

- 11. A method for making a hybrid receptor which receptor comprises (1) the ligand binding domain of a predetermined receptor and (2) a heterologous reporter polypeptide, said method comprising:
- (a) transforming a host cell with a vector containing nucleic acid encoding the hybrid receptor operably linked to a promoter for controlling the transcription of the hybrid receptor; and
- (b) culturing the host cell under conditions for 15 expressing the hybrid receptor.
 - 12. The method of claim 11 wherein the hybrid receptor is recovered from the culture medium of the host cell.
- 20 13. The method of claim 11 wherein the hybrid receptor is recovered from the cell membrane of the host cell.
 - 14. A method for assaying a biologically active ligand or an antagonist or agonist for said ligand, comprising:
- 25 (a) providing a hybrid receptor which comprises (1) a binding domain for the ligand, antagonist or agonist and (2) a heterologous reporter polypeptide;
 - (b) incubating the receptor with a test sample suspected to contain the ligand, antagonist or agonist;
- 30 (c) detecting a change in the reporter polypeptide; and
 - (d) correlating said change with the presence of the ligand, antagonist or agonist in the test sample.
- 35 15. The method of claim 14 wherein the ligand is a polypep-

tide and the ligand binding domain is not the antigen binding site of an immunoglobulin.

- 16. The method of claim 14 wherein the change in the 5 reporter polypeptide is a modification of the enzymatic activity of the polypeptide.
- 17. The method of claim 16 wherein the change in the reporter polypeptide is autophosphorylation of the reporter 10 polypeptide.
- 18. The method of claim 14 wherein the test sample is suspected to contain an antagonist and the receptor is incubated with the test sample and a predetermined activity 15 of ligand or ligand agonist.
 - 19. The method of claim 14 wherein the change in the reporter polypeptide is a change in an immune epitope.
- 20 20. The method of claim 19 wherein the change in immune epitope is detected by incubating the receptor with an antibody capable of binding to the reporter polypeptide and determining the amount of bound or residual unbound polypeptide.

- 21. The method of claim 14 wherein the reporter polypeptide further comprises a stable free radical, fluorescent or chemiluminescent group and the change in the reporter polypeptide is detected by measuring a change in the rotational 30 moment of the stable free radical or a change in the intensity, wavelength or polarization of the fluorescent or chemiluminescent group.
- 22. The method of claim 14 wherein the reporter polypeptide 35 is capable of binding to a G protein.
